Optimal form of retention for securitized loans under moral hazard

Georges Dionne and Sara Malekan

This version: November 27, 2015

Abstract

We address the moral hazard problem of securitization using a principal-agent model where the investor is the principal and the lender is the agent. Our model considers structured asset-backed securitization with a credit enhancement procedure. We assume that the originator can affect the default probability and the conditional loss distribution. We show that the optimal form of retention must be proportional to the pool default loss even in the absence of systemic risk when the originator can affect the conditional distribution of portfolio losses, yet the current regulations propose a constant retention rate.

Keywords

Securitization, optimal retention, moral hazard, principal-agent model, tranching, credit enhancement, conditional loss distribution.

1. Introduction

Despite all the advantages that securitization offers the economy and the financial system, the financial crisis that began in 2007 drew attention to the fact that advantageous financial innovations such as securitization can become a source of financial instability if industry practice and regulation do not keep pace with financial innovation (Selody and Woodman, 2009).

It is becoming important for regulators and market participants to understand the costs and benefits of securitization under moral hazard so they can improve the incentives and scope of securitization to mitigate the effects of this information problem. Berndt and Gupta (2009) believe that the highly deregulated nature of the secondary loan market is one of the main reasons for the occurrence of moral hazard and adverse selection problems. Stein (2011) explains the effect of unregulated private money creation on establishment of unstable markets, which requires the implementation of policy that supplements open-market operation.

Overall, tranche allocation is considered one of the most effective ways to align mutual benefits between originators and investors. Different retention mechanisms have very different impacts on originators' efforts and incentives in screening and monitoring borrowers. Two general types of retention are equity tranche retention and vertical slice retention.

Vertical slice retention by banks entails retaining a percentage share of each tranche. Equity slice retention is a horizontal percentage share of the equity tranche retention. Retention mechanisms have varying impacts on the screening level due to different sensitivities to the default risk factor, which plays an important role in determining borrowers' default probabilities and asset value (Fender and Mitchell, 2009a, 2009b). Showing different sensitivities implies that the effectiveness of tranche retention in aligning incentives should be a function of tranche thickness, asset return,

the size of the retained interest, the economy's position in the cycle (the state of the macro economy) and most importantly how the tranche retention is configured.

Selecting the optimal type of retention scheme is critical because the wrong scheme could cause unintended costs and consequently hamper efforts to establish sustainable securitization markets. It is also very important to determine the required retention amount wisely, based on precise calculations, which is the focus of our research. When retention requirements are too low, screening and monitoring incentives may not be sufficiently high, but if requirements are too high, securitization may no longer be an efficient form of structured finance (Selody and Woodman, 2009).

The United States and the European Union (EU) regulations require 5% of uniform and constant mandatory risk retention in the form of a vertical slice with a fixed ratio per tranche, or a horizontal slice of the most junior tranche (equity), or even a combination of both forms of retention (IMF, 2009; Sidley, 2014). Moreover, the regulation prohibits the hedging and transfer of the loss retained by the bank. This retention scheme has been criticized in recent papers. Most criticisms focus on vertical slice retention because it is not optimal for aligning incentives of financial intermediaries to monitor borrowers (Fender and Mitchell, 2009b; Kiff and Kisser, 2010). Jeon and Nishihara (2012) also point out the weakness of the risk retention requirement in terms of other aspects of the current regulation. They highlight the impact of fixed ratios on risk retention efficiency, which is uniformly applied to every financial institution, without considering features of individual intermediary or business cycle. Wu and Guo (2010) show the deficiency of a flat ratio of risk retention and suggest that the information disclosure requirement is more efficient than risk retention in this sense. Dugan (2010) claims that fixed risk retention worsens resource allocation and suggests a minimum underwriting standard requirement instead. Levitin (2013)

3

argues that flat risk retention cannot resolve the moral hazard problem of credit card securitization but that implicit recourse can. Batty (2011) asserts that the current regulation may shrink the issuance of collateralized loan obligations (CLOs) because most CLOs are actively managed by third-party managers.

Optimal security design can play an important role in resolving the moral hazard problem, which can revive the securitization market and ensure the optimality of the securitization process; this claim is backed by theoretical arguments (Albertazzi, Eramo, Gambacorta and Salleo, 2011). DeMarzo and Duffie (1999) investigated optimal security design, focusing on the trade-off between liquidity costs and retention costs. Hartman-Glaser, Piskorski and Tchistyi (2012) present an optimal mortgage-backed security design in a continuous basis model that balances the timing of payments with information quality. As for DeMarzo and Duffie (1999), they assume that the bank has a higher discount risk than investors do. We do not need this assumption in our model. Malekan and Dionne (2014) show that a fixed retention contract is optimal under moral hazard when the bank can affect only the loan default probability with its unobservable actions. In this paper, we extend this contribution by permitting the bank to affect the conditional loss distribution with its credit risk management activities such as screening and monitoring actions. We show that a fixed retention rate of the equity tranche is not optimal even when there is no systemic risk.

The next section describes our research design. Section 3 specifies the model of securitization under moral hazard in the presence of tranching, where the bank can affect the loan default probability along with the conditional loss distribution. Section 4 analyzes the optimal form of the securitization contract and Section 5 concludes the paper.

2. Design of optimal securitization under moral hazard

We investigate the optimal security design of structured products by analyzing explicit incentive contracting under moral hazard. Our goal is to address the moral hazard problem using a principal-agent model where the investor is the principal and the lender (bank or originator) is the agent. Moral hazard is often defined broadly as a conflict of interest between two parties who are interacting with each other, when it is not possible for the principal to determine the agent's behavior in detail. If investors could design a complete contract that specifies how banks should manage credit risk and what kind of information they should gather, there would be no significant residual moral hazard problem in securitization. In real life, credit risk management activities are not observed by investors, so in the absence of optimal contracting the originator's behavior will be distorted by selling loans to investors because the payment it receives does not depend on its credit risk management effort.

Securitization operates in a similar way to partial risk sharing. Without securitization, all the costs and benefits of credit risk management are internal to the bank, and incentives to screen and monitor, for example, are maximal. With full securitization, originators sell all their credit risk to a third party and do not bear the cost of loan or credit card default. The more the investors contribute to covering the default cost, the less incentive the lenders have to carefully screen and monitor borrowers. We show how we can mitigate moral hazard in credit risk management effort by specifying the form of optimal retention of the loan pool that lenders should keep to maintain their incentives under ex-ante moral hazard.

One difficulty is to consider the credit enhancement procedure explicitly in the tranching of financial products. Our contribution extends the model proposed by Malekan and Dionne (2014),

which incorporates a tranching and credit enhancement procedure in a model where the agent can affect only the loan default probability. We add the possibility of the lender's affecting the conditional loss distribution or the severity distribution of credit risk with its effort. For example, a bank may have a lesser incentive to reduce the likelihood of high loss given default when the contract is not optimal. The bank may also have fewer incentives to obtain the costly information necessary to fix the debt optimal collateral that would reduce the loss given default.

3. Derivation of the model

We consider a risk-averse originator or bank that manages a loan pool with a value normalized to 1. The loan pool is assumed to be large enough to diversify away the idiosyncratic risk. We suppose that the average default probability of a loan pool without systemic risk is $p(e)$, which is a function of credit risk management effort e. In the case of loan default there is a random conditional loss L in the interval [0, 1]: $0 \leq L \leq 1$. $(1-L)$ can be interpreted as a random recovery rate and L is the random loss given default. We assume $p(e)$ is decreasing and convex in effort:

$$p'(e) < 0, p''(e) > 0. \tag{1}$$

Moreover, the lender can also affect the conditional loss distribution $F(L|e)$ and its density $f(L|e)$. Since L is a loss variable, we assume that $F_e(L|e) > 0$ and $F_{ee}(L|e) > 0$ to obtain the desired first-order effect and convexity property of the principal-agent program with the first-order approach (Rogerson, 1985). Effort is costly for originators and non-observable by investors. The cost function is equal to $C(e)$ and is increasing and convex in e:

$$C(0) = 0, C'(e) > 0, C''(e) > 0.$$ (2)

The risk-free rate of interest is normalized to zero. We assume there are two tranches in the securitization scheme. The originator securitizes part of the loan pool as a senior tranche for risk-neutral and competitive investors. The amount of the senior tranche that is securitized is equal to $(1-\alpha)$, with a higher credit rating than the average of the loan pool and a lower interest rate equal to r_1. The originator can keep the α fraction of the loan pool as an equity tranche with a lower credit rating and interest rate r_2 higher than r_1 because the credit risk of the equity tranche is higher. This tranche absorbs the first percentage (α) of loan portfolio losses because tranching introduces a hierarchical order in the allocation of losses, as in a firm capital structure where equity holders are the first to absorb default loss. Our objective is to derive the optimal form of $\alpha(L)$. In the following sections, we write $\alpha(L) \equiv \alpha$ to simplify the notation but we will verify the dependence of α with respect to L in the optimal form of the contract.

3.1 Investors' objective function

The expected return (π_1) of investors in the senior tranche is equal to:

$$\pi_1 = (1-\alpha)(r_1 - S) - p(e)\left[\int_{\frac{\alpha r_2}{R}}^{1} (LR - \alpha r_2) f(L|e) dL + \int_{\alpha}^{1} (L - \alpha) f(L|e) dL \right].$$ (3)

The amount that investors are willing to pay for the securitized loan is equal to the expected value of the payoff, which is equal to $(1-\alpha)$ $(1+S)$. $(1+S)$ is the net expected rate of return on the loan pool considering the potential default risk of the loan pool. The gross expected return of the entire loan pool is $(1+R)$. $R - S$ is the expected return loss of the loan pool due to default risk under risk neutrality.

In the non-default state, the return for these investors is equal to $(1-\alpha)(1+r_1)$. If the loan pool

defaults, the α fraction that is kept by the originator absorbs initial losses on both interest and

capital. This means that the investors will lose something only if the amount of loss on interest or

capital or both is large enough to exhaust the equity tranche.

Investors will lose something on interest when $Loss * R > \alpha r_2$ or when $Loss > \alpha r_2 / R$, and the

amount they will lose is equal to $(LR - \alpha r_2)$, which is the amount that is not absorbed by the equity

tranche. Therefore, senior investors' expected loss on interest is equal to:

$$\int_{\frac{\alpha r_2}{R}}^{1} (LR - \alpha r_2) f(L|e) dL. \tag{4}$$

These investors will lose something on capital when $Loss > \alpha$ and the amount that they will lose

is equal to $(L - \alpha)$. The expected loss on capital is equal to:

$$\int_{\alpha}^{1} (L - \alpha) f(L|e) dL. \tag{5}$$

With full securitization, when $\alpha = 0$, the expected profit of senior investors is equal to:

$$\pi_I \equiv (r_1 - S) - p(e) \int_{0}^{1} L(1+R) f(L|e) dL, \tag{6}$$

meaning that they will sustain all the credit risk.

3.2 Participation constraint

To satisfy the participation constraint, the expected welfare of the originator in the presence of

securitization should be at least equal to $\bar{U}$. $\bar{U}$ is the best opportunity of the bank when considering

securitization. We assume the originator is risk averse with $U'(\bullet) > 0$ and $U''(\bullet) < 0$. It is well

known that this assumption does not affect the form of the optimal contract. Similar results can be

obtained under risk neutrality by adding a limited liability constraint (Bolton and Dewatripont,

2005). Moreover, U can also be interpreted as any concave payoff due to imperfections in the financial market (Froot et al, 1993). In the case of securitization, we can write the expected utility of the originator (equity tranche if $\alpha > 0$) as follows:

$$(1-p(e))U\left(R-(1-\alpha)(r_1-S)\right)+p(e)\left[\int_0^{\frac{\alpha r_2}{R}} U\left(R-(1-\alpha)(r_1-S)-LR-L\right)f(L|e)\,dL\right]+ \tag{7}$$

$$p(e)\left[\int_{\frac{\alpha r_2}{R}}^{\alpha} U\left(R-(1-\alpha)(r_1-S)-\alpha r_2-L\right)f(L|e)\,dL\right]+p(e)\left[\int_{\alpha}^{1} U\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\right)f(L|e)\,dL\right].$$

The expected return on the collateral loan pool when there is no default is equal to $(1+R)$, which can be divided between tranches with different credit ratings and different interest rates. Therefore, we have the following relationship between return on loan pool and return on different tranches:

$$1*(1+R) = (1-\alpha)(1+r_1)+\alpha(1+r_2). \tag{8}$$

When there is no default, the expected payoff of the originator is equal to $\alpha(1+r_2)+(1-\alpha)(1+S)-1$, which can be simplified by using equation (8) to $R-(1-\alpha)(r_1-S)$.

In the case of default, because the equity tranche absorbs initial losses on interest and capital, the conditional utility is equal to:

$$\int_0^{\frac{\alpha r_2}{R}} U\left(R-(1-\alpha)(r_1-S)-LR-L\right)f(L|e)\,dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U\left(R-(1-\alpha)(r_1-S)-\alpha r_2-L\right)f(L|e)\,dL \tag{9}$$

$$+\int_{\alpha}^{1} U\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\right)f(L)\,dLf(L|e)\,dL.$$

If the amount of loss is smaller than the expected return on equity tranche, $LR < \alpha r_2$, the originator loses LR on interest and L on capital. If it is greater, $LR > \alpha r_2$, the originator loses αr_2 on interest and will lose something on capital too, depending on the total loss amount. If the loss amount is greater than α, the originator loses αr_2 plus α.

9

Finally, the participation constraint can be written as follows. We assign λ as the Lagrange multiplier to the participation constraint:

$$\lambda : (1 - p(e)) U\left(R - (1-\alpha)(r_1 - S)\right) + \tag{10}$$

$$p(e)\int_0^{\frac{\alpha r_2}{R}} U\left(R - (1-\alpha)(r_1 - S) - LR - L\right) f(L|e)dL + p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - L\right) f(L|e)dL +$$

$$p(e)\int_{\alpha}^{1} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - \alpha\right) f(L|e)dL - C(e) = \overline{U}.$$

The bank will participate in securitization as long as the left-hand side of (10) is not lower than $\overline{U}$, its best alternative.

3.3 Incentive compatibility constraint

This constraint ensures the effectiveness of the originator's effort to screen and monitor loans, taking the moral hazard problem into account. By differentiating the payoff of the originator in (10) in the presence of securitization with respect to a credit risk management effort (first-order condition for choice of effort), we can write the incentive compatibility constraint as follows.

$$\mu : -p'(e) U\left(R - (1-\alpha)(r_1 - S)\right) + \tag{11}$$

$$p'(e)\int_0^{\frac{\alpha r_2}{R}} U\left(R - (1-\alpha)(r_1 - S) - LR - L\right) f(L|e)dL +$$

$$p'(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - L\right) f(L|e)dL + p'(e)\int_{\alpha}^{1} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - \alpha\right) f(L|e)dL +$$

$$p(e)\int_0^{\frac{\alpha r_2}{R}} U\left(R - (1-\alpha)(r_1 - S) - LR - L\right) f_e(L|e)dL + p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - L\right) f_e(L|e)dL +$$

$$p(e)\int_{\alpha}^{1} U\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - \alpha\right) f_e(L|e)dL = C'(e).$$

We can verify that the Lagrange multiplier μ of this constraint is positive under moral hazard.

3.4 Technology constraint

This constraint is used to ensure that there is no over-retention by excluding $\alpha > 1$ or negative

securitization $(1 - \alpha < 0)$. The constraint is described in detail in Appendix *A.1*.

$$\delta : \alpha \leq 1 \begin{cases} \delta = 0 \longrightarrow \alpha < 1 \\ \delta < 0 \longrightarrow \alpha \geq 1 \end{cases}. \tag{12}$$

In the remainder of the paper, we will concentrate on the case where $\alpha < 1$ to simplify the notation,

but note that over-retention can easily be excluded as a potential solution.

4. Optimal securitization contract model

The optimal amount and form of the structured asset-backed securitization contract is obtained by

solving the following maximization program:

Maximizing objective function (3) over $\tag{13}$
$$S, \alpha, e,$$

and under the following constraints:

- participation constraint (10);
- incentive compatibility constraint (11);
- technology constraint (12).

The principal proposes different values of *S* and α and the agent chooses *e* according to these

values until an optimum is reached.

4.1 No moral hazard: $\mu = 0$

First we assume that $\mu = 0$ when there is no moral hazard and $e = e^{**}$. Because investors observe e, they set its level at the full information level e^{**} by using the "take it or leave it" strategy. If we differentiate the program in (13) with respect to S, we have (writing e for e^{**}):

$$S: -(1-\alpha) + \lambda (1-p(e)) U'(R-(1-\alpha)(r_1-S))(1-\alpha) + \tag{13}$$

$$\lambda\, p(e)\int_0^{\frac{\alpha r_2}{R}} U'(R-(1-\alpha)(r_1-S)-LR-L)(1-\alpha)f(L|e)dL + \lambda\, p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)(1-\alpha)f(L|e)dL +$$

$$\lambda\, p(e)\int_{\alpha}^{1} U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(1-\alpha)f(L|e)dL = 0.$$

By solving the above equation, we can isolate $\dfrac{1}{\lambda}$ as follows:

$$\frac{1}{\lambda} = (1-p(e))\ U'\big(R-(1-\alpha)(r_1-S)\big) + \tag{15}$$

$$p(e)\int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)f(L|e)dL + p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(1-\alpha)f(L|e)dL +$$

$$p(e)\int_{\alpha}^{1} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)f(L|e)dL.$$

Differentiating with respect to α yields:

$$-(r_1-S) + p(e)\, r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right)\ + p(e)(1-F(\alpha)) + \lambda (1-p(e))\ U'(R-(1-\alpha)(r_1-S))\,(r_1-S) + \tag{16}$$

$$\lambda\, p(e)\int_0^{\frac{\alpha r_2}{R}} U'(R-(1-\alpha)(r_1-S)-LR-L)\,(r_1-S)\,f(L|e)dL +$$

$$\lambda\, p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)(r_1-S-r_2)f(L|e)dL +$$

$$\lambda\, p(e)\int_{\alpha}^{1} U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_1-S-r_2-1)f(L|e)dL = 0.$$

By solving this equation for $1/\lambda$, we obtain:

$$\frac{1}{\lambda} = \left\{ \begin{array}{l} \dfrac{(1-p(e))\ U'\big(R-(1-\alpha)(r_1-S)\big)\ (r_1-S)}{(r_1-S)-p(e)\ r_2\left(1-F\left(\alpha\dfrac{r_2}{R}\right)\right)\ -p(e)(1-F(\alpha))} + \\[4mm] \dfrac{p(e)\int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)\ (r_1-S)\ f(L|e)dL}{(r_1-S)-p(e)\ r_2\left(1-F\left(\alpha\dfrac{r_2}{R}\right)\right)\ -p(e)(1-F(\alpha))} + \dfrac{p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(r_1-S-r_2)f(L|e)dL}{(r_1-S)-p(e)\ r_2\left(1-F\left(\alpha\dfrac{r_2}{R}\right)\right)\ -p(e)(1-F(\alpha))} + \\[4mm] \dfrac{\lambda\ p(e)\int_{\alpha}^{1} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(r_1-S-r_2-1)f(L|e)dL}{(r_1-S)-p(e)\ r_2\left(1-F\left(\alpha\dfrac{r_2}{R}\right)\right)\ -p(e)(1-F(\alpha))}. \end{array}\right\} \tag{17}$$

By equalizing (15) and (17) together we get the following equation:

$$p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(-r_2)f(L|e)dL + p(e)\int_{\alpha}^{1} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(-r_2-1)f(L|e)dL = \tag{18}$$

$$-p(e)\ \left\{ r_2\left(1-F\left(\alpha\dfrac{r_2}{R}\right)\right)\ +(1-F(\alpha))\right\} \left\{ \begin{array}{l} (1-p(e))\ U'\big(R-(1-\alpha)(r_1-S)\big)+p(e)\int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)\ f(L|e)dL + \\[3mm] p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)f(L|e)dL + p(e)\int_{\frac{\alpha r_2}{R}}^{1} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)f(L|e)dL \end{array}\right\}.$$

$\alpha^{**}= 0$ solves this equation, meaning that positive retention is not necessary to maintain the appropriate incentives (see Malekan and Dionne, 2014, for more details). There is no need for an equity tranche in this framework.

4.2 Moral Hazard: $\mu > 0$

Now we assume that $\mu > 0$ because there is potential moral hazard. If we differentiate the program (13) with respect to S, we obtain:

$$S:- (1-\alpha)+\lambda \ (1-p(e)) \ U'\big(R-(1-\alpha)(r_1-S)\big)(1-\alpha)+ \tag{19}$$

$$\lambda \ p(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)(1-\alpha)f(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(1-\alpha)f(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(1-\alpha)f(L|e)dL \end{array} \right\}$$

$$-\mu \ p'(e) \ U'\big(R-(1-\alpha)(r_1-S)\big)(1-\alpha)+$$

$$\mu \ p'(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)(1-\alpha)f(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(1-\alpha)f(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(1-\alpha)f(L|e)dL \end{array} \right\}$$

$$+\mu \ p(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)(1-\alpha)f_e(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(1-\alpha)f_e(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(1-\alpha)f_e(L|e)dL \end{array} \right\}=0.$$

By simplifying the above equation, we obtain:

$$\frac{1}{\lambda p(e)+\mu p'(e)}=\frac{-U'\big(R-(1-\alpha)(r_1-S)\big)+\int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)f(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)f(L|e)dL+\int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)f(L|e)dL}{1-\lambda \ U'\big(R-(1-\alpha)(r_1-S)\big)-\mu \ p(e)\left\{ \begin{array}{l}\int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big)f_e(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)f_e(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)f_e(L|e)dL\end{array}\right\}}. \tag{20}$$

If we differentiate (13) with respect to α we have:

$$-(r_1-S)+p(e) \ r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right) + p(e)(1-F(\alpha))+\lambda \ (1-p(e)) \ U'\big(R-(1-\alpha)(r_1-S)\big) \ (r_1-S)+ \tag{21}$$

$$\lambda \ p(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big) \ (r_1-S) \ f(L|e)dL+ \\[2mm] \int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(r_1-S-r_2)f(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(r_1-S-r_2-1)f(L|e)dL \end{array} \right\}-\mu \ p'(e) \ U'\big(R-(1-\alpha)(r_1-S)\big) \ (r_1-S)+$$

$$\mu \ p'(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big) \ (r_1-S) \ f(L|e)dL+ \\[2mm] \int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(r_1-S-r_2)f(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(r_1-S-r_2-1)f(L|e)dL \end{array} \right\}+\mu \ p(e)\left\{ \begin{array}{l} \int_0^{\frac{\alpha r_2}{R}} U'\big(R-(1-\alpha)(r_1-S)-LR-L\big) \ (r_1-S) \ f_e(L|e)dL+ \\[2mm] \int_{\frac{\alpha r_2}{R}}^{\alpha} U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-L\big)(r_1-S-r_2)f_e(L|e)dL+ \\[2mm] \int_{\alpha}^1 U'\big(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\big)(r_1-S-r_2-1)f_e(L|e)dL \end{array} \right\}=0.$$

This can be simplified as follows:

$$-U'(R-(1-\alpha)(r_1-S))(r_1-S)+\int_0^{\frac{\alpha r_2}{R}}U'(R-(1-\alpha)(r_1-S)-LR-L)(r_1-S)f(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)(r_1-S-r_2)f(L|e)dL+ \quad (22)$$

$$\frac{1}{\lambda p(e)+\mu p'(e)}=\frac{\int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_1-S-r_2-1)f(L|e)dL}{(r_1-S)-\lambda\ U'(R-(1-\alpha)(r_1-S))(r_1-S)-p(e)\left\{r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right)+(1-F(\alpha))\right\}}$$

$$-\mu\ p(e)\left\{\begin{array}{l}\int_0^{\frac{\alpha r_2}{R}}U'(R-(1-\alpha)(r_1-S)-LR-L)(r_1-S)f_e(L|e)dL+\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)(r_1-S-r_2)f_e(L|e)dL+\\ \int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_1-S-r_2-1)f_e(L|e)dL\end{array}\right\}$$

By equalizing (20) and (22) together we get the following equation:

$$p(e)\left\{r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right)+(1-F(\alpha))\right\}\left\{\begin{array}{l}-U'(R-(1-\alpha)(r_1-S))+\int_0^{\frac{\alpha r_2}{R}}U'(R-(1-\alpha)(r_1-S)-LR-L)f(L|e)dL+\\ \int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)f(L|e)dL+\\ \int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)f(L|e)dL\end{array}\right\} \quad (23)$$

$$=$$

$$\mu\ p(e)\left\{\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-LR-\alpha)r_2f_e(L|e)dL+\int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_2+1)f_e(L|e)dL\right\}$$

$$+\{1-\lambda U'(R-(1-\alpha)(r_1-S))\}\left\{\begin{array}{l}\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)r_2f(L|e)dL+\\ \int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_2+1)f(L|e)dL\end{array}\right\}.$$

4.3 Analyzing the result

Our two objectives are to verify first if the optimal retention rate $\alpha^*>0$ under moral hazard and then if α^* is a function of L when the conditional loss distribution is affected by e. We use the following notations to simplify the presentation of the analysis:

$$x=\frac{\left\{\begin{array}{l}\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)r_2f(L|e)dL+\\ \int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_2+1)f(L|e)dL\end{array}\right\}}{\left\{r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right)+(1-F(\alpha))\right\}},x_e=\frac{dx}{de}=\frac{\left\{\begin{array}{l}\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)r_2f_e(L|e)dL+\\ \int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)(r_2+1)f_e(L|e)dL\end{array}\right\}}{\left\{r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right)+(1-F(\alpha))\right\}} \quad (24)$$

and

$$y=p(e)\int_0^{\frac{\alpha r_2}{R}}U'(R-(1-\alpha)(r_1-S)-LR-L)\ f(L|e)dL+$$

$$p(e)\int_{\frac{\alpha r_2}{R}}^{\alpha}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-L)f(L|e)dL+p(e)\int_{\alpha}^{1}U'(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha)f(L|e)dL.$$

When there is no moral hazard we obtain (25) using the above notations (Malekan and Dionne, 2014):

$$(1 - p(e)) \; U'\big(R - (1-\alpha)(r_1 - S)\big) = x - y \longrightarrow U'\big(R - (1-\alpha)(r_1 - S)\big) = \frac{x - y}{(1 - p(e))} . \tag{25}$$

In this case, $\alpha** = 0$ and the left-hand side of (25) is equal to $U'\big(R - (r_1 - S)\big)$. With moral hazard we have the following result using (24):

$$(\lambda x - p(e)) \; U'\big(R - (1-\alpha)(r_1 - S)\big) = x - y + \mu p(e) x_e \longrightarrow U'\big(R - (1-\alpha)(r_1 - S)\big) = \frac{x - y + \mu p(e) x_e}{(\lambda x - p(e))} . \tag{26}$$

To compare equations (25) and (26), we need to know the sign of x_e and the relative value of λx with respect to 1. Below we consider four cases to determine λx and the sign of x_e, which are necessary conditions to obtain the optimal α :

1) First we assume that $\lambda < \dfrac{1}{x}$ and $x_e < 0$:

In this case the comparison between equations (25) and (26) is impossible because both the numerator and the denominator of equation (26) decrease together when we add λx and x_e. We cannot determine the relation between $U'\big(R - (1-\alpha)(r_1 - S)\big)$ with respect to $U'\big(R - (r_1 - S)\big)$.

2) Second we assume that $\lambda < \dfrac{1}{x}$ and $x_e > 0$:

In this case, because the numerator of equation (26) increases and its denominator decreases, the right-hand side of (26) increases and $U'\big(R - (1-\alpha)(r_1 - S)\big)$ increases so:

$$U'\big(R - (1-\alpha)(r_1 - S)\big) > \frac{x - y}{(1 - p(e))} = U'\big(R - (r_1 - S)\big) . \tag{27}$$

16

U' is decreasing in its payoff under concavity and $r_1 > S$, which means that α must be less than or equal to zero to satisfy the inequality. Because α cannot be smaller than zero at the optimum, this means that there should be full securitization. By putting $\alpha = 0$ in the above inequality, we get the following result:

$$U'(R - r_1 + S) > U'(R - r_1 + S). \tag{28}$$

which is a contradiction, so we reject this possibility.

    3) Now we consider the third case, where $\lambda > \dfrac{1}{x}$ and $x_e > 0$:

In this case the comparison is again impossible, because both the numerator and the denominator of equation (26) increase simultaneously when we add λx and x_e.

    4) Finally, we consider the fourth case, where $\lambda > \dfrac{1}{x}$ and $x_e < 0$:

In this case the numerator of equation (26) decreases and its denominator increases, therefore $U'\big(R - (1-\alpha)(r_1 - S)\big)$ decreases and we obtain:

$$U'\big(R - (1-\alpha)(r_1 - S)\big) < \frac{x - y}{(1 - p(e))}. \tag{29}$$

Because U' is decreasing in its payoff and $r_1 > S$, this means that α should be greater than zero to solve this inequality. This implies that full securitization is not optimal and there must be positive retention (or an equity tranche held by the originator) under moral hazard. The optimal solution is $\alpha^* > 0$. The next step is to verify if α^* is a constant or a function of L.

In Malekan and Dionne (2014), the conditional loss distribution is not a function of e, so x_e was equal to zero. Consequently, the optimal form of the contract involved retaining a positive constant amount of the loan portfolio as an equity tranche (retention), calculated based on the parameters of the model. As has been shown above, the only acceptable case when $F_e(L|e) > 0$ is when x_e is negative:

$$x_e = \frac{dx}{de} = \frac{\left\{ \begin{array}{l} \int_{\frac{\alpha r_2}{R}}^{\alpha} U'\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - L\right) r_2 f_e(L|e) dL + \\ \left[\int_{\alpha}^{1} U'\left(R - (1-\alpha)(r_1 - S) - \alpha r_2 - \alpha\right)(r_2 + 1) f_e(L|e) dL \right] \end{array} \right\}}{\left\{ r_2\left(1 - F\left(\alpha \frac{r_2}{R}\right)\right) + (1 - F(\alpha)) \right\}} < 0. \tag{30}$$

To verify the consistency of (30) with the first-order approach, we now consider an example of distribution that satisfies the two properties that are sufficient for the first-order condition to be valid when the conditional distribution of loss is a function of e: the convexity of the distribution function with respect to effort $F_{ee} > 0$ and the monotone likelihood ratio property (MLRP) (Milgrom, 1981; Rogerson, 1985; Dionne and Spaeter, 2003; LiCalzi and Spaeter, 2013).

The MLRP assumption implies a monotonic relationship between effort and reward. We know that the exponential distribution is consistent with MLRP (Rogerson, 2005). We now consider this distribution for L. In addition, we assume constant risk aversion.

Because L is a random loss, as in Winter's (2013) study of the insurance context, we assume that $\frac{d}{dL}\left(\frac{f_e(L|e)}{f(L|e)}\right) < 0$ to obtain an optimal contract. This means that more effort reduces the likelihood of large losses. The intuition behind the MLRP assumption in our principal-agent model is that, because effort is not observable, observed loss will send uninformed investors, the principal in this

case, a sufficiently informative signal on the bank's unobservable effort so that they can require the agent to exert the optimal effort level. In other words, if effort shifts the loss distribution according to MLRP, then we can be confident that a lower level of observed loss will almost certainly indicate a higher level of agent effort. Then the principal can write a contract with a monotonic decreasing reward in loss, while the agent is expected to respond with a higher level of effort, and both parties will be better off.

In Appendix A.2, we verify that x_e is negative under MLRP and constant risk aversion. Moreover, we observe that x_e is a function of L. This means that we must consider the derivative of x_e with respect to L to obtain additional information on the optimal structure of securitization.

We can rewrite (26) in the following manner:

$$U'\big(R-\big(1-\alpha(L)\big)(r_1-S)\big)=\frac{x-y+\mu p(e)x_e(L)}{(\lambda x-p(e))}.$$ (31)

From the above analysis, we know that the numerator and the denominator of the right-hand side of (31) are positive. Moreover, μ and $p(e)$ are also positive. In Appendix A.3, we show that the derivative of x_e with respect to L is negative. So when L increases, x_e decreases as does $U'(\bullet)$ under risk aversion. This means that $R-\big(1-\alpha(L)\big)(r_1-S)$ increases when L increases, implying that $\alpha(L)$ increases with L because $r_1 > S$.

We now compare α_1^* with $\alpha_2^*(L)$, where α_1^* is the optimal retention rate with $F(L)$ and $\alpha_2^*(L)$ is the optimal retention function with $F(L|e)$. With conditional loss distribution as a function of effort we have the following optimal result:

$$U'\left(R-\left(1-\alpha_2^*(L)\right)\left(r_1-S\right)\right)=\frac{x-y+\mu p(e)x_e(L)}{\left(\lambda x-p(e)\right)}, \tag{33}$$

while we have the following result for the case where the conditional loss distribution is not a function of effort (Malekan and Dionne, 2014):

$$U'\left(R-(1-\alpha_1^*)\left(r_1-S\right)\right)=\frac{x-y}{\left(\lambda x-p(e)\right)}. \tag{34}$$

From (34), we have $\alpha_1^* > 0$. Because x_e is negative, for given values of x and y we get:

$$\frac{x-y}{\left(\lambda x-p(e)\right)} > \frac{x-y+\mu p(e)x_e(L)}{\left(\lambda x-p(e)\right)}, \text{ for all } L \geq \alpha_1^*. \tag{35}$$

Because U' is decreasing in wealth, this means that the optimal amount of retention with variable conditional loss distribution with respect to effort $\left(\alpha_2^*(L)\right)$ should be greater than the optimal amount of retention with constant conditional loss distribution (α_1^*).

Based on this relationship we can draw the following figure for investors loss by writing $\alpha_2^*(L)=\alpha_1^*+\beta L, \ 1<\beta<1$ since $\dfrac{d^2x_2^*(L)}{dL^2}=0$, as shown in Appendix A.3.

Investors will lose nothing when the amount of loss is smaller than $\alpha_2^*(L)\dfrac{r_2}{R}$. They will lose $\left(LR-\alpha_2^*(L)r_2\right)$ when $\alpha_2^*(L)\dfrac{r_2}{R}<L<\alpha_2^*(L)$. The slope of the line in this interval is equal to $\dfrac{R-\beta r_2}{1+R}$, which is smaller than the slope of the line with a fixed conditional distribution of loss that equals $\dfrac{1}{1+R}$. Investors loss is equal to $\left(L-\alpha_2^*(L)\right)+LR-\alpha_2^*(L)r_2$ when $L>\alpha_2^*(L)$ with a

slope equal to $\dfrac{1-\beta+R-\beta r_2}{1+R}$. The slope in this interval is larger than the previous slope but

smaller than 1 which is the slope of the line with a fixed conditional distribution of loss.

Figure 1: Optimal securitization contract with different assumptions on
conditional distribution of loss and credit enhancement
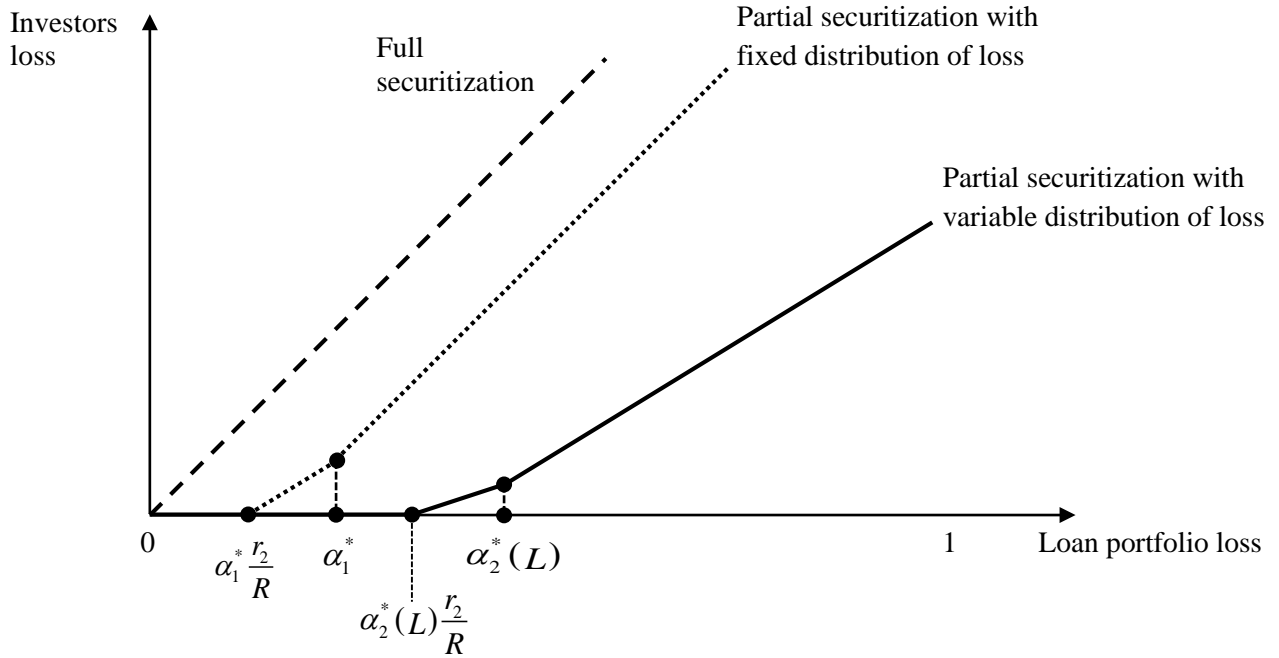

Notes: Investor loss equals 0 when $L < \alpha_2^*(L)\dfrac{r_2}{R}$, equals $\left(LR - \alpha_2^*(L)r_2\right)$ when

$\alpha_2^*(L)\dfrac{r_2}{R} < L < \alpha_2^*(L)$ and equals $\left(L - \alpha_2^*(L)\right) + LR - \alpha_2^*(L)r_2$ when $L > \alpha_2^*(L)$, and where

$\alpha_2^*(L) = \alpha_1^* + \beta L, \, 0 < \beta < 1.$

5. Conclusion

In this paper, we develop the security design methodology for structured asset-backed

securitization with a credit enhancement procedure and moral hazard to obtain the optimal risk

sharing design between sellers and buyers of these products. We first show that the optimal level of retention must be positive in the presence of credit enhancement and moral hazard.

We also show that the optimal form of retention differs according to the variation of conditional loss distribution with respect to effort. With constant conditional loss distribution, the optimal form of retention is constant equity tranche retention, whereas with a variable conditional loss distribution it is proportional to total loss.

The main intuition of our results is: To reduce the default probability and the loss given default (LGD) and ensure the investor's participation in these products, the originator will have more incentives to provide the optimal credit risk management activities if the observed loss provides sufficient information on realized effort. As a result, the optimal amount of retention must increase with loss to obtain the desired result.

For future research, we can take a step further by considering structured asset-backed securitization with a credit enhancement procedure in the presence of correlation between assets in the original pool, as observed during the recent financial crisis. Another possible extension is to derive the optimal retention for each security tranche and verify if the retention in each tranche increases with L. Such an extension is not trivial because it implies finding one optimal retention rate for each security tranche.

Appendix A

A.1 Technology constraint

If we can show the positivity of the first-order condition with respect to α at $\alpha^* = 1$, this implies that δ should be negative when it is binding, to rule out over-retention. Below we calculate the F.O.C with respect to α assuming $\alpha^* = 1$:

$$-(r_1 - S) + p(e) \; r_2 \left(1 - F\left(\frac{r_2}{R}\right)\right) + \lambda \; (1 - p(e)) \; U'(R) \; (r_1 - S) + \tag{A.1}$$

$$\lambda \; p(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \; (r_1 - S) \; f(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL \end{array} \right\} - \mu \; p'(e) \; U'(R) \; (r_1 - S) +$$

$$\mu \; p'(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \; (r_1 - S) \; f(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL \end{array} \right\} + \mu \; p(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \; (r_1 - S) \; f_e(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f_e(L|e)dL \end{array} \right\} > 0.$$

The negative terms in the above calculation are:

$$-(r_1 - S) - \lambda \; p(e) \; U'(R) \; (r_1 - S) + \mu \; p'(e) \left\{ \int_0^{\frac{r_2}{R}} U'(R - LR - L) \; (r_1 - S) \; f(L|e)dL + \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL \right\} \tag{A.2}$$

For each of the above negative terms, we have the positive terms with greater value to eliminate their effect:

$$\lambda \; U'(R) \; (r_1 - S) \tag{A.3}$$

$$\lambda \; p(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \; (r_1 - S) \; f(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL \end{array} \right\} \tag{A.4}$$

$$-\mu \; p'(e) \; U'(R) \; (r_1 - S). \tag{A.5}$$

In other words, we have the following:

$$-(r_1 - S) < \lambda \ U'(R) \ (r_1 - S) \tag{A.6}$$

because $\lambda U'(R)$ is greater than 1 under moral hazard (Malekan and Dionne, 2014), and

$$- \lambda \ p(e) \ U'(R) \ (r_1 - S) < \lambda \ p(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \ (r_1 - S) \ f(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL + \end{array} \right\} \tag{A.7}$$

$$\mu \ p'(e) \left\{ \begin{array}{l} \int_0^{\frac{r_2}{R}} U'(R - LR - L) \ (r_1 - S) \ f(L|e)dL + \\ \int_{\frac{r_2}{R}}^1 U'(R - r_2 - L)(r_1 - S - r_2)f(L|e)dL \end{array} \right\} < -\mu \ p'(e) \ U'(R) \ (r_1 - S) \tag{A.8}$$

because $U'(R)$ is decreasing. As a result we concluded that:

$$\text{F.O.C} > 0 \text{ at } \alpha^* = 1. \tag{A.9}$$

Therefore, the technology constraint must be binding (with $\delta < 0$) to rule out over-retention.

A.2 Specific distribution and constant risk aversion case

We assume constant risk aversion by using the following utility function:

$$U(w) = \frac{-a^{-bw}}{b}, U'(w) = a^{-bw} > 0, U''(w) = -ae^{-bw}. \tag{A.10}$$

where b is the measure of constant risk aversion and a is an exponential function. We also assume that L follows the distribution function $F(L|e) = L^{-e}$. This distribution was proposed by Rogerson (1985). For two other distributions with the MLRP, see LiCalzi and Spaeter (2013). First, we need to compute the MLRP to make sure that the optimality conditions are satisfactory. As discussed above, we need a negative MLRP, which is a sufficient assumption to obtain the optimal contract with the first-order approach. We also need to verify that the second derivative of the loss distribution function is positive (CDFC).

$$F_e(L|e) = -(\ln(L))L^{-e} > 0 \qquad\qquad (A.11)$$

$$F_{ee}(L|e) = (\ln(L))^2 L^{-e} > 0.$$

We can calculate the MLRP:

$$\frac{d}{dL}\left(\frac{f_e(L|e)}{f(L|e)}\right) = \frac{d}{dL}\left(\frac{-(\ln(L))L^{-e}}{L^{-e}}\right) = -\frac{1}{L} < 0. \qquad\qquad (A.12)$$

Considering constant risk aversion we now compute x_e. Under our assumptions, x_e is equal to:

$$x_e = \frac{dx}{de} = \frac{r_2 \int_{\frac{\alpha r_2}{R}}^{\alpha} a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-L\right)} f_e(L|e)dL + (1+r_2)a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\right)}(\ln\alpha)\alpha^{-e}}{\left\{ r_2\left(1-F\left(\alpha\frac{r_2}{R}\right)\right) + (1-F(\alpha))\right\}}. \qquad (A.13)$$

Because $\dfrac{\alpha r_2}{R} < L < \alpha$ and $a^{bL} < a^{b\alpha}$, we have the following:

$$r_2 \int_{\frac{\alpha r_2}{R}}^{\alpha} a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-L\right)} f_e(L|e)dL < r_2 a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\right)}[-(\ln\alpha)\alpha^{-e} + (\ln\alpha\frac{r_2}{R})(\alpha\frac{r_2}{R})^{-e}]. \qquad (A.14)$$

The right-hand side of the above inequality is negative, because:

$$\alpha\frac{r_2}{R} < \alpha \qquad\qquad (A.15)$$

$$\ln\alpha\frac{r_2}{R} < \ln\alpha$$

$$(\alpha\frac{r_2}{R})^{-e} > \alpha^{-e}$$

$$-(\ln\alpha)\alpha^{-e} + (\ln\alpha\frac{r_2}{R})(\alpha\frac{r_2}{R})^{-e} < 0.$$

This means that the left-hand side is also negative.

A.3 Derivative of x_e with respect to L

The derivative of x_e in (A.13) with respect to L is equal to:

$$-r_2 a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\alpha\right)} \ln \alpha(\alpha)^{-e} + r_2 a^{-b\left(R-(1-\alpha)(r_1-S)-\alpha r_2-\frac{\alpha r_2}{R}\right)} \ln\frac{\alpha r_2}{R}(\frac{\alpha r_2}{R})^{-e}.$$

Because $\frac{\alpha r_2}{R}<\alpha$, this means that $\frac{dx_e}{dL}<0$. This expression is not a function of L so $\frac{d^2 x_e}{dL^2}=0$

under our assumptions.
